Script-Controlled ACL: Restricting Record Access Based on Field Value

2. Development, Testing & Implementation Phase

The second phase focuses on implementing the ACL and validating the access logic in ServiceNow. The ACL is configured for the required table and operation, such as read or write, and the script evaluates the relevant field on the current record.

The implementation approach is to first validate the user's required role and then evaluate the record field value. When the configured rule is satisfied, the ACL returns an allowed result; otherwise, access is denied. This provides an additional layer of record-level security.

The project user story is: **As a ServiceNow administrator, I want to test the scripted ACL with different users and field values so that the access rule works correctly before it is moved to production.**

Testing includes authorized users, unauthorized users, records with matching field values, records with non-matching values, and records where the field is empty. The solution should also be checked for direct record access and other applicable interfaces.

The final implementation should include clear documentation of the field used, roles or groups involved, expected access behavior, and test results. The completed solution provides a controlled and repeatable method for restricting record access based on business-defined field values.
